Abstract

We present a method for synthesizing recursive functions that provably satisfy a given specification in the form of a refinement type. We observe that such specifications are particularly suitable for program synthesis for two reasons. First, they support automatic inference of rich universal invariants, which enables synthesis of nontrivial programs with no additional hints from the user. Second, refinement types can be decomposed more effectively than other kinds of specifications, which is the key to pruning the search space of candidate programs. To support such decomposition, we propose a new algorithm for refinement type inference, which is applicable to partial programs.

We have evaluated our prototype implementation on a large set of synthesis problems and found that it exceeds the state of the art in terms of both scalability and usability. The tool was able to synthesize more complex programs than those reported in prior work (several sorting algorithms, binary-search tree manipulations, red-black tree rotation), as well as most of the benchmarks tackled by existing synthesizers, often starting from a more concise and intuitive user input.

Keywords Program Synthesis, Functional Programming, Refinement Types, Predicate Abstraction

1. Introduction

The key to scalable program synthesis is modular verification. Modularity enables the synthesizer to prune inviable candidate subprograms independently, whereby combinatorially reducing the size of the search space it has to consider. This explains the recent success of *type-directed* approaches

to synthesis of functional programs [1, 7, 9, 10, 20]: not only do well-typed programs vastly outnumber ill-typed ones, but more importantly, a type error can be detected long before the whole program is put together.

Simple, coarse-grained types alone are, however, rarely sufficient to precisely describe a synthesis goal; existing approaches supplement type information with other kinds of specifications, such as input-output examples [1, 7, 20], pre/post-conditions [13, 15], or executable assertions [10]. Alas, the corresponding verification procedures rarely enjoy the same level of modularity as type checking, thus fundamentally limiting the scalability of these techniques.

In this work, we present a system called SYNQUID that pushes the idea of type-directed synthesis one step further by taking advantage of *refinement types* [8, 25]: types decorated with predicates from logics efficiently decidable by SMT solvers. For example, type `Nat` can be defined as a refinement over the simple type `Int`, $\{\nu: \text{Int} \mid \nu \geq 0\}$, where the predicate $\nu \geq 0$ restricts the type to those values that are greater than or equal to zero¹. Base refinement types, such as `Nat`, can be combined into *dependent function types*, written $x: T_1 \rightarrow T_2$, where the formal argument x may appear in the refinement predicates of T_2 .

Verification techniques based on refinement types—in particular, the *liquid types* framework [12, 25, 29, 30]—have been successful at checking nontrivial properties of programs with little to no user input. Piggybacking quantifier-free predicates on top of types makes it possible to rely on the type system for automatically generalizing and instantiating rich universal invariants, while leaving the SMT solver to deal with subsumption queries over simple predicates. For example, the type `List Nat` encodes a universal invariant that all elements of a list are natural numbers; when a list of this type is constructed or, conversely, scrutinized, the type system automatically decomposes such an invariant into properties over individual list elements, simple enough to be expressed with quantifier-free predicates, and it does so using no other input than the type of the `Cons` constructor. The key insight behind SYNQUID is that program synthesis can harness the unique ability of refinement type systems to decompose complex specifications into simpler properties over

[Copyright notice will appear here once 'preprint' option is removed.]

¹ Hereafter the bound variable of the refinement is always called ν and the binding is omitted.

subexpressions in order to prune the space of candidate programs more effectively than what can be achieved by input-output examples or even pre/post-conditions.

In SYNQUID the user specifies a synthesis goal by providing a type signature. For example, the function `replicate` can be specified as follows:

$$n : \text{Nat} \rightarrow x : \alpha \rightarrow \{\text{List } \alpha \mid \text{len } \nu = n\}$$

Given an integer n and a value x of type α , `replicate` produces a list of length n where every value is of type α . The specification could be further strengthened with the constraint that each list element must be equal to x by changing the type parameter of the list to $\{\alpha \mid \nu = x\}$. Somewhat surprisingly, this would be redundant: since the type parameter α can be instantiated with *any refinement type*, the specification above guarantees that whatever property x might have (including the property of having a particular value), every element of the list will share that same property. Thus, the type as written above fully specifies the behavior of the function and is only marginally more complex than a conventional ML or Haskell type. We argue therefore that (within the domain of their applicability) refinement types offer a convenient interface to a program synthesizer; in particular, they are as straightforward and often more concise than input/output examples, especially considering that state-of-the-art example-based systems often require about a dozen examples to get the correct implementation [20].

In addition to the type signature, our algorithm takes as input an environment of functions and inductive datatypes that the synthesized program can use as components. Each of these components is described purely through its type signature: implementations of component functions need not be available.

As demonstrated by the specification of `replicate`, *parametric polymorphism* is crucial to the expressiveness of refinement types, providing means to abstract (quantify) over refinements. The liquid types inference algorithm [25] makes it possible to instantiate polymorphic types automatically, using a combination of Hidley-Milner-style unification with predicate abstraction, which is a key ingredient in automating the verification. Predicate abstraction constructs values of unknown refinements as conjunctions of atomic predicates called *qualifiers*, in general, provided by the user (in practice, however, qualifiers can almost always be extracted automatically from the types of components and the specification).

Unfortunately, liquid type inference in its existing form is impractical in the context of synthesis, since it does not fully exploit the modularity of refinement type checking: first, it only propagates type information bottom-up and, second, it requires a Hidley-Milner unification pass over the whole program before inferring refinements.

The needs of synthesis prompt us to develop a new type checking mechanism, which would propagate specifications

```
replicate :: n:Nat → x:α → {List α | len ν = n}
replicate = λ n . λ x . if n ≤ 0
  then Nil
  else Cons x (replicate (dec n) x)
```

Figure 1. Code synthesized from the type signature of `replicate`

top-down as much as possible and be applicable to incomplete programs. The new mechanism, which we dub *modular refinement type reconstruction*, is enabled by a combination of an existing *bidirectional* approach to type checking (which, however, has not been previously applied in the context of general decidable refinement types) and a novel, *incremental* algorithm for liquid type inference, which gradually discovers the shape and the refinements of unknown types as it analyzes different parts of the program. By making type checking as local as possible, the new mechanism facilitates scalable synthesis through interleaving generation and verification of candidate programs at a very fine level of granularity.

To make full use of top-down propagation of type information, the predicate abstraction engine of SYNQUID has to discover *weakest* refinements instead of strongest, as in liquid types, which is fundamentally more expensive. A secondary contribution of this paper is a practical technique for doing so, which relies on an existing mechanism for enumerating minimal unsatisfiable subsets [16].

The ability to discover weakest refinements naturally extends to inferring environment assumptions that are necessary to make a given solution correct. This search strategy, most commonly known as *condition abduction*, has been proven effective in prior work [2, 13, 15]; in SYNQUID it comes at virtually no cost since it is simply a byproduct of typechecking.

The combination of explicit candidate enumeration, modular checking, and condition abduction enables our system to produce an implementation of `replicate` shown in Fig. 1 in under a second. Sec. 2 shows how these techniques extend naturally to synthesizing programs that manipulate data structures with complex invariants (such as sorted and unique lists, binary search trees, heaps, and red-black trees) and use higher-order functions (such as maps and folds).

In total, we have evaluated SYNQUID on 52 different synthesis problems from a variety of sources. Our evaluation indicates that SYNQUID can synthesize programs that are more complex than those previously reported in the literature, including four different sorting algorithms, binary search tree manipulations, and red-black tree rotation. We also show that refinement types are expressive enough to specify a broad range of problems. We compare SYNQUID with its competitors, based on input-output examples, expressive specifications, and test harnesses, and demonstrate that we can handle the majority of their most challenging

benchmarks. Compared to the state-of-the-art tools based on input-output examples, our specifications are usually more concise and we generate provably correct code. Compared to the tools based on deductive reasoning, we can handle more complex reasoning due to refinement inference. More broadly, our system demonstrates a new milestone in the use of expressive type systems to support program synthesis, showing that expressive types do not have to make a programmer's life harder, but can in fact help automate some aspects of programming.

Our implementation and an online interface are available from the SYNQUID repository [24].

2. Overview

Consider a core ML-like language featuring conditionals, algebraic datatypes, **match**, ML-style polymorphism, and **fixpoints**. We equip our language with *general decidable refinement types*, closely following the liquid types framework [12, 25, 29]. Values of a base type B are described as $\{B \mid \psi\}$, where ψ is a *refinement predicate* over the program variables and a special *value variable* ν , which does not appear in the program. Functions are described using dependent types of the form $x: T_1 \rightarrow T_2$, where x may appear in the refinement predicates of T_2 . Our framework is *agnostic* to the exact logic of refinement predicates as long as validity of subsumption in this logic can be decided; examples in this paper use QFAUFLIA (the quantifier-free logic of arrays, uninterpreted functions, and linear integer arithmetic), as does our prototype implementation.

Synthesis procedure. The synthesis problem is given by (a) a goal refinement type (b) an environment, which initially contains a set of type signatures for component datatypes and functions, and (c) a set of qualifiers.

Depending on the goal type, our system performs one of the following steps: it either decomposes the synthesis problem into subproblems (with a simpler goal and/or enriched environment), or it switches to the guess-and-check mode, in which it enumerates all well-typed terms that have the desired *type shape*—i.e. the type stripped of its refinements—and then issues a *subtyping constraint* to make sure that the guess fulfills the goal. As in several previous approaches that rely on explicit exploration (e.g. [9, 20]), the terms are enumerated in order of increasing size and syntactically restricted to β -normal η -long form.

Importantly, even in the guess-and-check mode, our system does not abandon refinements completely; rather it uses the type system to automatically decompose the goal specification into properties that can be further propagated top-down and those that can only be checked after the whole term is constructed. In addition, since guessing only enumerates terms that are well-typed in our refinement type system, the preconditions of component functions serve as filters for candidate arguments that can be applied right away. The *early filtering* enabled by these two features is key to the

scalability of our synthesis procedure, which is confirmed by our evaluation (Sec. 4).

Solving subtyping constraints. Due to polymorphic components, in a subtyping constraint $\Gamma \vdash T' <: T$, the types T and T' may contain free type variables α_i ; the interpretation of such a constraint is two-fold: (i) the shapes of T and T' must have a unifier in the traditional Hindley-Milner sense [22] and (ii) once the shapes are unified, the refinements of T' must subsume the ones of T . The subsumption constraints, in turn, may contain *predicate unknowns* κ_i , which stand for unknown refinements of the types introduced during unification or unknown branch conditions in the environment Γ . For example, a subtyping constraint $\alpha <: \text{Nat}$ gives rise to a unifier $[\alpha \rightarrow \{\text{Int} \mid \kappa_0\}]$, where κ_0 is a fresh predicate unknown, and to a subsumption constraint $\kappa_0 \Rightarrow \nu \geq 0$. Our system uses a greatest-fixed-point predicate abstraction procedure to assign to each κ_i the smallest conjunction of qualifiers that validates all the subsumption constraints; if no such assignment exists, it rejects the candidate program.

Issuing subtyping constraints early only helps if they can be solved early too. Polymorphism make this challenging: previous approaches to refinement type reconstruction [14, 25] rely on a whole-program shape inference phase to completely determine the shapes of all the types before they can insert predicate unknowns and proceed with refinement inference. Instead, our system solves subtyping constraints *incrementally, interleaving the two phases*. For example, a constraint $\alpha <: \{\text{List } \beta \mid \psi\}$, where both α and β are free type variables, will result in partial shape reconstruction, leading to a unifier $[\alpha \rightarrow \{\text{List } \gamma \mid \kappa_0\}]$, a subsumption constraint $\kappa_0 \Rightarrow \psi$, and another subtyping constraint $\gamma <: \beta$, to be solved later, as the shape of β is recovered.

The rest of the section goes through a series of examples that demonstrate various features of our type system and illustrate the synthesis procedure outlined above.

Example 1: Recursion and conditionals. We first revisit the replicate example from the introduction. We assume that the set of available components includes functions \emptyset , inc and dec on integers, as well as a generic list datatype whose constructors are refined with length information, expressed by means of an uninterpreted function len , also called a *measure*:

```

 $\emptyset :: \{\text{Int} \mid \nu = 0\}$ 
 $\text{inc} :: x: \text{Int} \rightarrow \{\text{Int} \mid \nu = x + 1\}$ 
 $\text{dec} :: x: \text{Int} \rightarrow \{\text{Int} \mid \nu = x - 1\}$ 

measure  $\text{len} :: \text{List } \beta \rightarrow \text{Nat}$ 
data  $\text{List } \beta$  decreases  $\text{len}$  where
   $\text{Nil} :: \{\text{List } \beta \mid \text{len } \nu = 0\}$ 
   $\text{Cons} :: \beta \rightarrow xs: \text{List } \beta \rightarrow$ 
     $\{\text{List } \beta \mid \text{len } \nu = \text{len } xs + 1\}$ 

```

The **decreases** annotation above enables recursion on lists by defining a *termination metric*, which maps lists to a type

that has a predefined well-founded order in our language and thus can be used in termination checks. Examples in this paper integrate measure-based refinements (and termination metrics) with datatype definitions for simplicity; [12] shows how a measure definition can be syntactically decoupled from its datatype and then desugared automatically into the above representation, thus, allowing a single datatype to be decorated with multiple, custom measures depending on the problem at hand.

For the rest of the section, let us fix the set of qualifiers \mathbb{Q} to $\{\star \leq \star, \star \geq \star, \star \neq \star\}$, where \star is a placeholder that can be instantiated with any program variable or ν .

Given the specification

$$n: \text{Nat} \rightarrow x: \alpha \rightarrow \{\text{List } \alpha \mid \text{len } \nu = n\}$$

SYNQUID first performs a **decomposition step**: it adds $n: \text{Nat}; x: \alpha$ to the environment and proceeds to synthesize a body of type $\{\text{List } \alpha \mid \text{len } \nu = n\}$. This decomposition step does not restrict the search, since every terminating program has an equivalent β -normal η -long form, where all functions are fully applied and the head of each application is a variable. SYNQUID also makes the function recursive in the first argument (but not the second), since its type shape Int has an associated well-founded order; to this end, the tool extends the environment with a binding $\text{replicate}: (m: \{\text{Int} \mid 0 \leq \nu < n\} \rightarrow y: \alpha \rightarrow \{\text{List } \alpha \mid \text{len } \nu = m\})$ (note the weakened type, which only allows calling replicate with arguments strictly smaller than n).

When synthesizing the body of replicate , SYNQUID first adds a fresh predicate unknown κ_C to the set of environment assumptions, which stands for the guard of the current branch. It then starts enumerating candidate application terms t of shape $\{\text{List } \alpha\}$ from simplest to more complex, and for each t it issues a subtyping constraint to check if the candidate has the desired refined type. In our example, the simplest list term is Nil ; this choice results in a subtyping constraint $n: \text{Nat}; x: \alpha; \kappa_C \vdash \{\text{List } \alpha \mid \text{len } \nu = 0\} <: \{\text{List } \alpha \mid \text{len } \nu = n\}$ which reduces to the subsumption constraint: $0 \leq n \wedge \kappa_C \wedge \text{len } \nu = 0 \Rightarrow \text{len } \nu = n$. At this point, SYNQUID uses predicate abstraction to find the weakest valid *liquid assignment* to all predicate unknowns, that is, the smallest conjunction of qualifiers from \mathbb{Q} , instantiated with all suitable variables in scope, that makes the subsumption constraint hold. If such a weakest assignment is a contradiction, the candidate is discarded. In the example, predicate abstraction discovers the assignment $\mathcal{L} = [\kappa_C \mapsto n \leq 0]$, effectively abducting the necessary branching condition. Since the condition is not trivially true, the system proceeds to synthesize the **else**-branch of the conditional under the fixed assumption $\neg \mathcal{L}[\kappa_C]$. The technique for synthesizing branching programs based on condition abduction it has been successfully employed in several program synthesis tools [2, 13, 15], but to our knowledge SYNQUID is the first one to use predicate abstraction to systematically discover optimal branch conditions.

The remaining branch has to deal with the harder case of $n > 0$. When enumerating application terms for this branch, SYNQUID eventually decides to apply the replicate components (that is, make a recursive call). At this point, the strong precondition on the argument m , $0 \leq \nu < n$, which arises from the termination requirement, enables filtering candidate arguments locally, before synthesizing the rest of the branch. In particular, the system will discard the candidates n and $\text{inc } n$ right away, since they fail to produce a value strictly less than n .

Example 2: Complex data structures and invariant inference. Assuming comparison operators in our logic are generic, we can define the type of binary search trees as follows:

```
measure keys :: BST  $\alpha$   $\rightarrow$  Set  $\alpha$ 
data BST  $\alpha$  decreases keys where
  Empty :: {BST  $a \mid$  keys  $\nu = []$ }
  Node ::  $x: \alpha \rightarrow l: \text{BST } \{\alpha \mid \nu < x\} \rightarrow r: \text{BST } \{\alpha \mid x < \nu\}$ 
          $\rightarrow \{\text{BST } \alpha \mid \text{keys } \nu = \text{keys } l + \text{keys } r + [x]\}$ 
```

This definition states that one can obtain a binary search tree either by taking an empty tree, or by composing a node with key x with two binary search trees, l and r , in which all keys are, respectively, strictly less and strictly greater than x . The type is additionally refined by the measure keys , which denotes the set of all keys in the tree.

The following type specifies insertion into a binary search tree:

```
insert ::  $x: \alpha \rightarrow t: \text{BST } \alpha \rightarrow$ 
         $\{\text{BST } \alpha \mid \text{keys } \nu = \text{keys } t + [x]\}$ 
```

From this specification, SYNQUID generates the following implementation (where some symbols are numbered for future reference):

```
insert =  $\lambda x. \lambda t. \text{match } t \text{ with}$ 
  | Empty  $\rightarrow$  Node  $x$  Empty Empty
  | Node  $y \ l \ r \rightarrow$  if  $x \leq y \wedge y \leq x$ 
    then  $t$ 
    else if  $y \leq x$ 
      then Node1  $y \ l \ (\text{insert}^1 \ x \ r)$ 
      else Node2  $y \ (\text{insert}^2 \ x \ l) \ r$ 
```

The challenging aspect of this example is reasoning about sortedness. For example, in order for $\text{Node}^1 \ y \ l \ (\text{insert}^1 \ x \ r)$ to be type-correct, the recursive call must have the type $\text{BST } \{\alpha \mid y < \nu\}$; this type is not implied by the user-provided signature for insert , and in fact only makes sense for this particular call site, since it mentions a local variable y . Inferring this type amounts to discovering a complex inductive property of insert , namely that inserting a key that is greater than some value z into a tree with keys greater than z again produces a tree with keys greater than z . The requirement to infer such complex invariants puts this and similar examples beyond reach of existing systems that synthesize provably correct code, such as LEON.

In our framework, this property is easily inferred using the combination of polymorphic recursion and automatic instantiation of type variables by means of predicate abstraction. When `insert` is added to the environment, its type is generalized into $\forall \beta.x: \beta \rightarrow t: \text{BST } \beta \rightarrow \{\text{BST } \beta \mid \text{keys } \nu = \text{keys } t + \{x\}\}$. At the site of the recursive call, β is instantiated with $\{\alpha \mid \kappa_0\}$; here the shape of β is determined by unification, but the refinement is unknown. Enforcing the precondition of `Node`¹ $y \mid$ leads predicate abstraction to discover the liquid assignment $[\kappa_0 \mapsto y < \nu, \kappa_C \mapsto y \leq x]$ (where κ_C is the current branch guard), whereby simultaneously instantiating the polymorphic recursive call and abducting the branch condition.

Example 3: Abstract refinements. Using refinement types an interface to synthesis raises the question of their expressiveness. Restricting refinements to decidable logics fundamentally limits the class of programs they can fully specify, and for other programs writing a refinement type might be possible but cumbersome compared to providing a set of input-output examples or a specification in a richer language. The previous examples have shown that refinement types are the right tool for specifying programs that manipulate data structures with nontrivial universal and inductive invariants. In this example we demonstrate how extending the type system with *abstract refinements* allows us to express a wider class of properties, for example, talk about the order of list elements.

Abstract refinements, proposed in [29], enable explicit quantification over refinements of datatypes and function types. For example, the `List` datatype can be parameterized by a binary predicate P , which describes the relation between every in-order pair of elements in the list:

```
data List a (P::a → a → Bool) where
  Nil::List a P
  Cons::x:a → xs:List {a | P x ν} P → List a P
```

On the one hand, as shown in [29], this enables concise definitions of list with various inductive properties; for example, increasing and unique lists can now be defined as an instantiations $\text{InclList } \alpha = \text{List } \alpha(\leq)$ and $\text{Unilist } \alpha = \text{List } \alpha(\neq)$, respectively.

On the other hand, making list-manipulating functions polymorphic in this predicate, provides a concise way to specify order-related properties. Consider the following type for list reversal:

```
reverse::(P::a → a → Bool) . xs:List a P →
  {List a (λxλy. P y x) | len ν = len xs}
```

It says that whatever relation holds between every *in-order* elements of the input list, also has to hold between every *out-of-order* elements of the output list. This type does not restrict the applicability of `reverse`, since at the call site P can always be instantiated with `True`; the implementation of `reverse`, however, has to be correct to any value of P , which leaves the synthesizer no choice but reverse the order of list

elements. Given the above specification and a component that appends an element to the end of the list (specified in a similar fashion), `SYNQUID` synthesizes the standard implementation of list reversal.

[29] has also shown that abstract refinements make it possible to give a precise type to `foldr`, which folds a binary function over a list. Using the type they proposed, `SYNQUID` is able to synthesize both the standard implementation of `foldr`, as well as non-recursive implementations of standard list functions, such as `length` or `append` that use `foldr`. Synthesizing the higher-order argument to `foldr` presents no problem to `SYNQUID`, since it can be treated as a separate synthesis goal.

3. The SYNQUID Language

The goal of this section is to develop a high-level formalization of the procedure outlined in Sec. 2 in the form of *synthesis rules*. In doing so we follow previous work on type-directed synthesis [10, 20], which has shown how to turn type checking rules for a language into synthesis rules for the same language, by reinterpreting each rule that generates a type given a term as generating a term given a type.

We first present the syntax and static semantics of our core language with refinement types (Sec. 3.1); the language is based on `NANOML` developed within the liquid types framework [12, 25], thus our presentation skips common details, focusing on the differences. In the interest of space we omit abstract refinements (see Sec. 2) from the formalization; [29] has shown that integrating this mechanism into the type system that already supports parametric polymorphism is straightforward. Sec. 3.2 describes the core technical contribution of our paper: the *modular refinement type reconstruction* algorithm, which combines the ideas of bidirectional type checking [23] with an incremental procedure for solving subtyping constraints. Finally, Sec. 3.3 presents the synthesis rules derived from the modular type reconstruction rules.

3.1 Syntax and types

Fig. 2 shows the syntax of `SYNQUID`.

Terms. Unlike previous work, we differentiate between the languages of refinements and programs. The former consists of refinement terms ψ , which have sorts Δ ; the exact set of interpreted symbols and sorts depends on the chosen refinement logic. We refer to refinement terms of the Boolean sort \mathbb{B} as formulas.

The language of programs consists of program terms t , which we split, following [6, 20] into *elimination* (E-term) and *introduction* (I-term) forms. Intuitively, E-terms—variables and applications—propagate information bottom-up, *composing* a complex property from properties of their components; I-terms propagate information top-down, *decomposing* a complex requirement into simpler requirements for their components.

ψ	$::= (\text{varies})$	<i>Refinement term:</i>
Δ	$::=$ $\mathbb{B} \mid \mathbb{Z} \mid \dots$ (<i>varies</i>)	<i>Sort:</i> interpreted uninterpreted
t	$::=$ e $\lambda x.t$ if e then t else t match e with $ _i C_i \langle x_i^j \rangle \mapsto t_i$ fix $x.t$	<i>Program term:</i> E-term abstraction conditional match fixpoint
e	$::=$ x $e t$	<i>E-term:</i> variable application
B	$::=$ $\text{Bool} \mid \text{Int}$ D^m α	<i>Base type:</i> primitive datatype type variable
\mathbb{T}^\square	$::=$ $\{B \mathbb{T}_i^\square \mid \square\}$ $x : \mathbb{T}^\square \rightarrow \mathbb{T}^\square$	<i>Type Skeleton</i> base function
\mathbb{S}^\square	$::= \forall \alpha_i. \mathbb{T}^\square$	<i>Schema Skeleton</i>
τ, σ	$::= \mathbb{T}^\square, \mathbb{S}^\square$	<i>Unref. Type, Schema</i>
T, S	$::= \mathbb{T}^\psi, \mathbb{S}^\psi$	<i>Ref. Type, Schema</i>

\hat{S}	$::= \forall \alpha_i. \hat{T}$	<i>Contextual Ref. Schema</i>

Figure 2. Syntax

Types and Schemas. Type and schema skeletons are parametrized by the space of refinements. Instantiating this space with a unit yields unrefined types and schemas; instantiating it with formulas ψ yields refinement types and schemas. The shape of a type T , obtained by erasing all refinements, is denoted $\text{shape}(T)$.

A user-defined datatype is modeled as a base type D^m of arity $m \geq 0$ (other base types have an implicit arity of 0). Datatype constructors are represented simply as functions that must have the type $\forall \alpha_1 \dots \alpha_m. T_1 \rightarrow \dots \rightarrow T_k \rightarrow D \alpha_1 \dots \alpha_m$.

In a dependent function type $x : T_1 \rightarrow T_2$, T_2 may reference the formal argument x , which goes out of scope once the function is applied. The usual way of eliminating this variable is to give an application $t_1 t_2$ the type $[t_2/x]T_2$, which requires equipping the language with **let**-expressions and λ -normalizing the program, such that every t_2 is a variable. This approach is not suitable for SYNQUID, since it requires synthesizing arguments to unknown functions. To address this problem we introduce *contextual types*: the purpose of a contextual type $\text{let } x : T_1 \text{ in } T_2$, is to propagate the information about the formal argument x , which later can be used when deciding subtyping.

A *type environment* Γ is a sequence of path conditions ψ and variable bindings $x : T$.

Judgments. Our type system has four kinds of judgments: well-formedness, liquidness, subtyping, and typing. A for-

Type Inference	$\boxed{\Gamma \vdash_Q t :: \hat{S}}$
VARB	$\frac{\Gamma(x) = \{B \mid \psi\}}{\Gamma \vdash_Q x :: \{B \mid \nu = x\}}$
VARV	$\frac{\Gamma(x) = \forall \alpha_i. T \quad \Gamma \vdash_Q T_i}{\Gamma \vdash_Q x :: [T_i/\alpha_i]T}$
APPB	$\frac{\Gamma \vdash_Q e_1 :: \text{let } C_1 \text{ in } (x : \{B \mid \psi\} \rightarrow T) \quad \Gamma; C_1 \vdash_Q e_2 :: \text{let } C_2 \text{ in } T_x \quad \Gamma; C_1; C_2 \vdash T_x <: \{B \mid \psi\}}{\Gamma \vdash_Q e_1 e_2 :: \text{let } C_1; C_2; y : T_x \text{ in } [y/x]T}$
APP	$\frac{\Gamma \vdash_Q e :: \text{let } C_1 \text{ in } (_ : T_x \rightarrow T) \quad \Gamma; C_1 \vdash_Q t :: T'_x \quad \Gamma; C_1 \vdash T'_x <: T_x}{\Gamma \vdash_Q e t :: \text{let } C_1 \text{ in } T}$
ABS	$\frac{\Gamma \vdash_Q (x : T_x \rightarrow T) \quad \Gamma; x : T_x \vdash_Q t :: \hat{T}' \quad \Gamma \vdash \hat{T}' <: T}{\Gamma \vdash_Q \lambda x.t :: (x : T_x \rightarrow T)}$

Figure 3. Liquid type inference for SYNQUID programs

mula ψ is *well-formed* in the environment Γ , written $\Gamma \vdash \psi$, if it is of a Boolean sort and all its free variables are bound in Γ . A formula ψ is *liquid* in Γ with qualifiers \mathbb{Q} , written $\Gamma \vdash_Q \psi$, if it is a conjunction of well-formed formulas, each of which is obtained from a qualifier in \mathbb{Q} by substituting \star placeholders by variables. Both of those judgment are extended to types in a standard way. The *subtyping* judgment $\Gamma \vdash T_1 <: T_2$ is also standard.

The *typing* judgment $\Gamma \vdash_Q t :: \hat{S}$ states that the term t has (contextual) type schema S in the environment Γ using qualifiers \mathbb{Q} . Fig. 3 presents type checking rules for SYNQUID, which are based on liquid type checking for NANOML.

The distinction between the terms with constructible types and those with liquid types is present in the original liquid type system; in SYNQUID it corresponds to the distinction between E-terms and I-terms: E-terms have constructible (possibly contextual) types, while I-terms have liquid (non-contextual) types. Note that the rule VARV, which handles polymorphic instantiations, is special: it is the only E-term rule that requires creating a fresh liquid type.

SYNQUID has two separate rules for first-order (APPB) and higher-order (APP) application, since only in the first

case the formal argument of the function may appear in its result type, and thus must be bound using a contextual type.

The final distinction between SYNQUID and NANOML lies in the rule for fixpoints, which in our case comes with a termination check. In the context of synthesis, termination concerns are impossible to ignore, since non-terminating recursive programs are always simpler than terminating ones, and thus would be synthesized first if considered correct. The `FIX` rule gives the “recursive call” a termination-weakened type $S^<$, which intuitively denotes “ S with strictly smaller arguments”.

3.2 Modular Refinement Type Reconstruction

Type inference rules presented above are impractical to use in the context of synthesis. First, type inference only propagates type information *bottom-up*. In the context of synthesis this amounts to enumerating all well-typed terms of a given shape, and the checking the inferred type of a complete term against the specification. With this approach the benefit of refinement types for guiding the synthesis is only minimal compared to simple types. It is clearly desirable to propagate refinement types *top-down* whenever possible. For example, in order to check $\Gamma \vdash_{\mathbb{Q}} \text{if } \hat{\psi} \text{ then } t_1 \text{ else } t_2 :: T$, it is sufficient to check that both t_1 and t_2 have the type T (under appropriate path conditions). The type system should make it possible to reject this program in case t_1 fails the check, before even considering t_2 .

Second, practical algorithms for refinement type inference employ a two-phase approach to inferring polymorphic instantiations: in the *shape reconstruction* phase the shape of T is determined using Hindley-Milner-style unification [22]; in the second phase, *refinement inference*, the previously found shape is used to create a template for T by inserting fresh *predicate unknowns* in place of refinements; after reducing subtyping constraints to subsumption over known and unknown refinements, the values of predicate unknowns are found by means of predicate abstraction. Since Hindley-Milner unification is *global*, the whole program must be available before the refinement inference phase can even start.

In this section we develop a type reconstruction algorithm for SYNQUID that tackles these two challenges.

Bidirectional type reconstruction. We address the first challenge by combining liquid type inference with the ideas from *bidirectional type checking* [23]. The use of bidirectional type checking for synthesis was pioneered by [20] in the context of simple types augmented with input-output examples; in the realm of richer type systems, it has been employed for type reconstruction of various flavors of refinement types [5, 6, 32] and general dependent types [4]. To the best of our knowledge, the present work is the first to suggest using bidirectional checking for type reconstruction of general decidable refinement types, as present in the liquid types framework.

The idea of bidirectional reconstruction is to interleave top-down and bottom-up propagation of type information depending on the syntactic structure of the program, with the goal of making type checks as local as possible. Bidirectional typing rules use two kinds of typing judgments: an *inference* judgment $\Gamma \vdash_{\mathbb{Q}} t \Rightarrow S$ states that the term t generates type schema S in the environment Γ ; a *checking* judgment $\Gamma \vdash_{\mathbb{Q}} t \Leftarrow S$ states that the term t checks against a known schema S in the environment Γ .

The bidirectional typing rules for SYNQUID are given in Fig. 4. The rules are split into two categories: inference rules have an inference judgment as their conclusion and encode the way the types of E-terms are constructed from their components types (bottom-up propagation); checking rules encode the way a checking judgment for an I-term is decomposed into simpler checking judgments for their components (top-down propagation). The rule I-E bridges the two directions: whenever an E-term e is being checked against a known type T , the type system switches to inference mode and then checks that the generated type of e is a subtype of T .

Incremental constraint solving. In order to turn the rules of Fig. 4 into a practical type reconstruction algorithm, we have to eliminate the remaining source of non-determinism: polymorphic instantiation. To do so, we replace the rule E-VAR \forall with a deterministic rule that replaces the universally quantified type variable with a fresh free type variable:

$$\text{E-VAR}\forall\text{-ALG} \frac{\Gamma(x) = \forall \alpha_i. T \quad \alpha'_i \text{ not free in } \Gamma \quad \Gamma \vdash_{\mathbb{Q}} \alpha'_i}{\Gamma \vdash_{\mathbb{Q}} x \Rightarrow [\alpha'_i / \alpha_i] T}$$

With this rule, free type variables α'^2 may appear in places of “generated” refinement types in the typing and subtyping judgments of the rules in Fig. 4.

This section details our technique for *solving* subtyping constraints with free type variables, that is, finding a type assignment that maps those variables to liquid types in a way that validates subtyping judgments, or concluding that such an assignment does not exist.

Unlike existing approaches [14, 25], our algorithm interleaves the phases of shape reconstruction and refinement inference. It maintains the current set of subtyping constraints \mathcal{C} , the current *type assignment* $\mathcal{T}: \alpha' \rightarrow T$ and the current *liquid assignment* $\mathcal{L}: \kappa \rightarrow \psi$. At each step, the refinement type reconstruction algorithm may either decide to apply one of the inference or checking rules of Fig. 4, whereby possibly adding a new constraint to \mathcal{C} , or it may pick and remove an arbitrary c from \mathcal{C} and solve it; solving c results either in failure (and conclusion that the program is ill-typed) or in extending \mathcal{T} , extending or strengthening \mathcal{L} , and/or adding new constraints to \mathcal{C} . This process is formalized in the procedure `Solve` in Fig. 5.

² We prime the names of free type variables to differentiate them from the universally quantified type variables of the outermost specification type.

$$\begin{array}{c}
\textbf{Type Inference} \quad \boxed{\Gamma \vdash_Q e \Rightarrow \hat{T}} \\
\\

\end{array}$$

Figure 4. Bidirectional type reconstruction for SYNQUID programs

Intuitively, Solve does one of the following, depending on the operands of a subtyping constraint: it either substitutes a type variable for which an assignment already exists (Eq. 1, Eq. 2), unifies a type variable with a type (Eq. 4, Eq. 5), decomposes subtyping over compound types (Eq. 6, Eq. 7), or repairs an invalid refinement subsumption by strengthening \mathcal{L} (Eq. 8). The type reconstruction algorithm terminates when the entire type derivation is built, and any attempt to solve a constraint $c \in \mathcal{C}$ only inserts c back into \mathcal{C} (that is, only Eq. 3, Eq. 9 apply).

During unification of α' and T , procedure Fresh inserts fresh predicate unknowns in place of all refinements in T ; note that due to the incremental nature of our algorithm, T might itself contain free type variables, which are simply replaced with fresh free type variables to be unified later as more subtyping constraints arise. For a fresh predicate unknown κ , $\mathcal{L}(\kappa)$ is initialized with an empty conjunction, and the search space for κ is derived from the liquidness constraints issued by the rule E-VAR \forall -ALG.

$$\begin{array}{l}
\text{Solve}(\Gamma \vdash c) = \text{match } c \text{ with} \\
| \{\alpha' \mid \psi\} <: T, \alpha' \in \text{dom}(\mathcal{T}) \longrightarrow \\
\quad \mathcal{C} \leftarrow \mathcal{C} \cup \{\Gamma \vdash \text{Refine}(\mathcal{T}(\alpha'), \psi) <: T\} \quad (1) \\
| T <: \{\alpha' \mid \psi\}, \alpha' \in \text{dom}(\mathcal{T}) \longrightarrow (\text{symmetrical}) \quad (2) \\
| \{\alpha' \mid \psi_1\} <: \{\beta' \mid \psi_2\} \longrightarrow \\
\quad \mathcal{C} \leftarrow \mathcal{C} \cup \{\alpha' \mid \psi_1\} <: \{\beta' \mid \psi_2\} \quad (3) \\
| \{\alpha' \mid \psi\} <: T, \alpha' \notin T \longrightarrow \\
\quad \mathcal{T} \leftarrow \mathcal{T} \cup [\alpha' \rightarrow \text{Fresh}(T)]; \\
\quad \mathcal{C} := \mathcal{C} \cup \{\Gamma \vdash \{\alpha' \mid \psi\} <: T\} \quad (4) \\
| T <: \{\alpha' \mid \psi\} \longrightarrow (\text{symmetrical}) \quad (5) \\
| (x: T_x \rightarrow T_1) <: (y: T_y \rightarrow T_2) \longrightarrow \\
\quad \mathcal{C} \leftarrow \mathcal{C} \cup \{\Gamma \vdash T_y <: T_x, \\
\quad \quad \Gamma; y: T_y \vdash [y/x]T_1 <: T_2\} \quad (6) \\
| \{D^m T_1^i \mid \psi_1\} <: \{D^m T_2^i \mid \psi_2\} \longrightarrow \\
\quad \mathcal{C} \leftarrow \mathcal{C} \cup \{\Gamma \vdash \{D^m \mid \psi_1\} <: \{D^m \mid \psi_2\}, \\
\quad \quad \Gamma \vdash T_1^i <: T_2^i\} \quad (7) \\
| \{B \mid \psi_1\} <: \{B \mid \psi_2\}, \neg(\llbracket \Gamma \rrbracket \wedge \psi_1 \Rightarrow \psi_2) \longrightarrow \\
\quad \mathcal{L} \leftarrow \text{Strengthen}(\mathcal{L}, \llbracket \Gamma \rrbracket \wedge \psi_1 \Rightarrow \psi_2) \quad (8) \\
| \{B \mid \psi_1\} <: \{B \mid \psi_2\}, \llbracket \Gamma \rrbracket \wedge \psi_1 \Rightarrow \psi_2 \longrightarrow \\
\quad \mathcal{C} \leftarrow \mathcal{C} \cup \{\Gamma \vdash \{B \mid \psi_1\} <: \{B \mid \psi_2\}\} \quad (9) \\
| \text{otherwise} \longrightarrow \text{fail} \quad (10)
\end{array}$$

Figure 5. Incremental constraint solving

As an example, starting from empty \mathcal{T} and \mathcal{L} , Solve($\vdash \alpha' <: \text{List } \beta' \mid \text{len } \nu > 0$) instantiates α' by Eq. 4 leading to $\mathcal{T} = [\alpha' \rightarrow \{\text{List } \gamma' \mid \kappa_0\}]$ and recycles the subtyping constraint; next by Eq. 1 and Eq. 7, the constraint is decomposed into $\vdash \text{List } \mid \kappa_0 <: \text{List } \mid \text{len } \nu > 0$ and $\vdash \gamma' <: \beta'$. If further type reconstruction produces a subtyping constraint on β' , say $\text{Nat} <: \beta'$, \mathcal{T} will be extended with an assignment $[\beta' \rightarrow \{\text{Int } \mid \kappa_1\}]$, which in turn will lead to transforming the constraint on γ' into $\vdash \gamma' <: \{\text{Int } \mid \kappa_1\}$ and instantiating $[\gamma' \rightarrow \{\text{Int } \mid \kappa_2\}]$, at which point all free type variables have been eliminated.

Predicate abstraction. The Strengthen procedure denotes the predicate abstraction step: Strengthen($\mathcal{L}, \psi_1 \Rightarrow \psi_2$) makes sure that $\psi_1 \Rightarrow \psi_2$ holds by strengthening $\mathcal{L}(\kappa)$ for some conjunct κ of the left-hand-side, or fails if that is not possible. Finding weakest solutions for predicate unknowns is more expensive than finding strongest solutions, as in liquid types (exponential instead linear in the number of qualifiers [27]). In order to be practical, our implementation of Strengthen uses MARCO: an efficient algorithm for enumerating all minimal unsatisfiable cores due to Liffiton et al. [16].

3.3 Modular Program Synthesis

With a modular type reconstruction calculus at hand, we can now propose a modular synthesis calculus, following the approach of [20]. Bidirectional synthesis rules use two kinds of synthesis judgments. a *refinement-directed synthesis* judgment $\Gamma \vdash_Q T \rightsquigarrow t$ states that in the environment Γ , refinement type T is inhabited by term t ; for example, the rule for generating a conditional is:

$$\text{SI-IF} \frac{\Gamma \vdash_Q \kappa \quad \Gamma; \kappa \vdash_Q T \rightsquigarrow t_1 \quad \Gamma; \neg \kappa \vdash_Q T \rightsquigarrow t_2}{\Gamma \vdash_Q T \rightsquigarrow \text{if } \kappa \text{ then } t_1 \text{ else } t_2}$$

A *shape-directed synthesis* judgment $\Gamma \vdash_Q \tau \rightsquigarrow t :: T$ states that in the environment Γ , shape τ is inhabited by term t of type T (such that $\text{shape}(T) = \tau$); for example, the rule for generating a variable is:

$$\text{SE-VAR} \frac{\tau = B \quad \Gamma(x) = \{B \mid \psi\}}{\Gamma \vdash \tau \rightsquigarrow x :: \{B \mid \nu = x\}}$$

Since the transformation from type checking rules is straightforward, we omit the rest of the rules.

4. Evaluation

We performed an extensive experimental evaluation of SYNQUID with the goal of assessing usability and scalability of the proposed synthesis technique compared to existing alternatives. This goal materializes into the following research questions:

- (1) Are refinement types supported by SYNQUID *expressive* enough to specify interesting programs, including benchmarks proposed in previous work?
- (2) How *concise* are SYNQUID’s input specifications compared both to the synthesized solutions and to inputs required by existing techniques?
- (3) Are SYNQUID’s inputs *intuitive*, in particular, is the algorithm applicable to specifications not tailored for synthesis?
- (4) How *scalable* is SYNQUID: can it handle benchmarks tackled by existing synthesizers? Can it scale to more complex programs than those previously reported in the literature?
- (5) How is synthesis performance impacted by various features of the type system and implementation?

4.1 Benchmarks

In order to answer the research questions above, we arranged a benchmark suite that consists of 52 synthesis challenges from various sources, representing a range of problem domains. In the interest of direct comparison with existing synthesis tools, our suite includes benchmarks that had been used in the evaluation of these tools [1, 2, 7, 13, 15, 18, 20]. From each of these papers, we picked top three most complex challenges (judging by synthesis times) that were ex-

pressible in SYNQUID’s refinement logic, plus possibly several easier problems that we found very common or particularly interesting.

Our second source of benchmarks are verification case studies from the Liquid Types literature [11, 29]. The purpose of this second category is two-fold: first, these problems are larger and more complex than existing synthesis benchmarks, and thus can show whether SYNQUID goes beyond the state of the art in synthesis; second, the specifications for these problems have been written by independent researchers and for a different purpose, and thus can serve as evidence that input accepted by SYNQUID is sufficiently general and intuitive. We picked the benchmarks that came with sufficiently strong functional specifications (omitting, for example, a case study that only checked array access bounds), erased all implementations, and made straightforward syntactic changes in order to obtain valid SYNQUID input.

Tab. 1 lists the 52 benchmarks together with some metrics of our type-based specifications: the cumulative size of refinements and the number of components and measures.

Note that the reported specification size only includes refinements in the signature of the synthesis goal; refinements in component functions are excluded since every such function (except trivial arithmetic operation) serves as the synthesis goal of another benchmark; refinements in datatype definitions are also excluded, since those definitions are reusable between all benchmarks in the same problem domain. Detailed descriptions and full specifications are available from the SYNQUID repository [24].

The benchmarks are drawn from a variety of problem domains with the goal of exercising different features of the system. Integer benchmarks showcase reasoning about primitive types; in particular, the programs calculating the maximum of N integers have emerged as a yardstick for the performance of condition abduction techniques [2, 18], since the search space of branch guards in these problems grows exponentially with N . List and tree benchmarks demonstrate pattern matching, structural recursion, the ability to generate and use polymorphic and higher-order functions (such as `map` and `fold`), as well as reasoning about nontrivial properties of data structures, both universal (e.g. all elements are non-negative) and recursive (e.g. size and set of elements). Our most advanced benchmarks include sorting and operations over data structures with complex representation invariants, such as binary search trees, heaps, and balanced trees; these benchmarks showcase expressiveness of refinement types, exercise SYNQUID’s ability to perform nontrivial reasoning through refinement discovery, and represent a scalability challenge beyond the current state of the art in synthesis. Finally, we included several benchmarks operating on “custom” datatypes in order to demonstrate that SYNQUID’s applicability is not limited to standard textbook examples.

Table 1. Benchmarks and SYNQUID results. For each benchmark, we report its *Name*; size of *Specification* and synthesized *Code* (in AST nodes); number of defined measures (*#m*) and provided components (*#cmp*); as well as SYNQUID running times (in seconds) in minimal context (*T-all*), in default context (*T-def*), with no incremental solving (*T-nis*), with no consistency checking (*T-ncc*), with no UNSAT-core-based predicate abstraction (*T-nuc*), with no memoization (*T-nm*). *t/o* denotes timeout of 2 minutes.

4.2 Results

Evaluation results are summarized in [Tab. 1](#). SYNQUID was able to synthesize (and fully verify) solutions for all 52 benchmarks; the table lists sizes of these solutions in AST nodes (*Code*) as well as synthesis times in seconds (*T-all*).

The results demonstrate that SYNQUID is efficient in synthesizing a variety of programs: 45 out of 52 benchmarks are synthesized within 3 seconds; it also scales to programs of nontrivial size, including complex recursive (binary-search tree insertion of size 55) and non-recursive functions (tripleton binary heap constructor of size 271). Even though specification sizes for some (simpler) benchmarks approach the size of the synthesized code, the benefits of describing computations as refinement types grow significantly with the complexity of the problem at hand: for example, the type-based specification of the three main operations over binary-search trees is over six times more concise than their implementation.

The synthesis times discussed above were obtained in a minimal context, which could differ across benchmarks. We also report synthesis times for a default context (column *T-def* of [Tab. 1](#)), where all benchmarks in the same category share the same exploration bounds and condition qualifiers. Although this inevitably slows down synthesis, on most of the benchmarks the performance penalties were not drastic: only one benchmark failed to terminate within the two-minute timeout.

In order to assess the impact on performance of various aspects of our algorithm and implementation, [Tab. 1](#) reports synthesis times using four variants of SYNQUID, where certain features or optimizations were disabled: incremental solving of subtyping constraints within the boundaries of an E-term (*T-nis*), checking consistency of function’s type with the current goal (*T-ncc*), using UNSAT-core-based MARCO algorithm to find weakest refinements in the predicate abstraction procedure (*T-nuc*), and memoization of enumerated E-terms (*T-nm*). The results demonstrate that the most significant contribution comes from using MARCO: 31 out of 52 benchmarks time out if it is replaced with the naive breadth-first search, since in that case condition abduction becomes infeasible even with a moderate number of atomic predicates.

The second most significant feature is incremental constraint solving, with 14 benchmarks timing out when disabled. Note that this variant of the algorithm only postpones solving the constraints that arise within an application term until that term is fully determined, effectively disabling the early filtering provided by function preconditions and top-down propagation of type parameters through applications; it retains top-down propagation of types through I-terms. Performing type reconstruction completely bottom up would prevent all but the simplest benchmarks from being synthesized within the time limit. As for the remaining two features, consistency checks only bring significant speedups for

	<i>Benchmark</i>	<i>Spec</i>	<i>SpecS</i>	<i>Time</i>	<i>TimeS</i>
LEON	strict sorted list delete	14	8	15.1	0.13
	strict sorted list insert	14	8	14.1	0.25
	merge sort	10	11	14.3	2.5
JEN	BST find	51	6	64.8	0.12
	bin. heap singleton	80	6	61.6	2.21
	bin. heap find	76	6	51.9	0.54
MYTH	sorted list insert	12	8	0.12	0.28
	list rm adjacent dupl.	13	5	0.07	0.47
	BST insert	20	8	0.37	1.71
λ^2	list remove duplicates	7	8	231	0.70
	list drop	6	14	316.4	0.18
	tree find	12	6	4.7	0.13
ESC	list rm adjacent dupl.	n/a	5	1	0.44
	tree create balanced	n/a	7	0.24	0.13
	list duplicate each	n/a	7	0.16	0.65
AL*	max of 4	n/a	15	1.57	0.48
	max of 5	n/a	19	4.15	5.54
PUF	max of 4	n/a	15	0.1	0.48
	max of 5	n/a	19	0.18	5.54

Table 2. Comparison to other synthesizers. For each benchmark we report: *Spec*, specification size (or the number of input-output examples) for respective tool; *SpecS*, specification size for SYNQUID (from [Tab. 1](#)); *Time*, reported running time for respective tool; *TimeS*, running time for SYNQUID (from [Tab. 1](#)).

the most complex examples (red-black trees), while the impact of memoization is minor throughout the benchmarks, suggesting that integrating a complex, stateful verification procedure into the search prevents effective reuse of enumeration results.

4.3 Comparative evaluation

We compared SYNQUID with all state-of-the-art synthesis tools that are capable of generating a similar class of programs and offer a comparable level of automation. The results are summarized in [Tab. 2](#). For each tool, we list the three most complex benchmarks reported in the respective work that were expressible in SYNQUID’s refinement logic; for each of the three benchmarks we report the specification size (if available) and the synthesis time; for ease of comparison, we repeat the same two metrics for SYNQUID (copied over from [Tab. 1](#)). Note that the synthesis times are not directly comparable, since the results for other tools are taken from respective papers and had been obtained on different hardware; however, the differences of an order of magnitude or more are still significant, since they cannot be explained by improvements in single-core hardware performance.

We split the tools into three categories according to the specification and verification mechanism they rely on, and discuss evaluation results separately for each group.

Formal specifications with deductive verification. The first category includes LEON [\[13\]](#) and JENNISYS [\[15\]](#); both

tools use pre- and post-conditions (and data structure invariants) to describe computations, and rely on unbounded, SMT-based verification to validate candidate programs (and thus provide the same correctness guarantees as SYNQUID). Unlike LEON and SYNQUID, Jennisys targets imperative, heap-based programs, which is a harder problem; the evaluation in [15], however, focuses on side-effect free benchmarks. Both tools use variants of condition abduction, which makes their exploration strategies similar to SYNQUID’s; instead of explicit enumeration, LEON uses CEGIS [26] to search for application terms and relies on testing for early pruning.

For both tools, translating their three most complex benchmarks into SYNQUID proved to be straightforward. This shows that our decidable refinement logic is not a significant limitation in practice: specifications that are easy to express with quantifiers and recursive predicates are just as easy to express with refinement types. Our specifications are on average slightly more concise than LEON’s and significantly more concise than those in JENNISYS; the latter is largely due to the heap-based language, but the results still indicate that embedding predicate into types can help curb the verbosity of traditional Hoare-style specifications.

SYNQUID is able to synthesize solutions to all problems tackled by the two tools in this category; the converse is not true: SYNQUID’s refinement inference enables invariant discovery, which is not supported by the other two tools, and is required for automatic verification of many complex benchmarks (such as Example 2 in Sec. 2); thus SYNQUID *qualitatively* differs from its competitors in terms of the class of programs for which a verified solution can be synthesized. On the benchmarks where the other tools are applicable, SYNQUID also outperformed them by at least an order of magnitude, which suggests that fast verification and early pruning enabled by type-based specifications indeed improve the scalability of synthesis.

Input/output examples. Our second category of tools includes MYTH [20], λ^2 [7] and ESCHER [1], which synthesize programs from concrete input-output examples. Using refinement types, we were able to express 3 out of 3, 10, and 5 of their most complex benchmarks, receptively. The functions we failed to specify either manipulate nested structures in a representation-specific way (such as “insert a tree under each leaf of another tree”), perform filtering (“list of nodes in a tree that match a predicate”), or require reasoning about list elements at specific positions (“insert element at a given position”). Some of these benchmarks can be covered by extending the refinement logic with sequences and set comprehensions.

At the same time, we found cases where refinement types are concise and intuitive, while providing input-output examples is extremely tedious. One of those cases is insertion into a binary search tree: in MYTH it requires 20 examples, each of which contains two bulky tree instances and has to

define the precise position where the new element is to be inserted; the type-based specification for this problem, given in Sec. 2, is straightforward and only defines the abstract effect of the operation relevant for the user. In general, all logic-based specification techniques, including refinement types, are better at describing operations that maintain a complex representation invariant but have a simple abstract effect, while example-based approaches are useful when describing operations that expose the complex representation of a data structure.

Experiments with example-based tools only report the number of examples required for synthesis and not their sizes; however, we can safely assume that each example contains multiple AST nodes, and thus conclude that type-based specifications for the benchmarks in Tab. 2 are more concise. By imposing more constraints on the set of examples (such as *trace completeness* [20]) and increasing its size, example-based synthesizers can trade off user effort for synthesis time. On the benchmarks under comparison, MYTH appears to favor performance, while λ^2 prefers smaller example sets; SYNQUID offers the best of both world and achieves good performance with concise specifications.

Constraints and bounded checking. In order to evaluate scalability of SYNQUID’s condition abduction mechanism on large search spaces, we compared it with PUFFIN [2] and ALLOY* [18] on a series of programs that compute the maximum of N integers. Both tools rely on CEGIS-like techniques, and use bounded verification through encoding into SAT. SYNQUID performs comparably to ALLOY*, while PUFFIN appears to scale better on these benchmarks. Note however, that these tools are unable to synthesize recursive functions, and thus qualitatively differ from SYNQUID.

5. Related Work

Our work is the first to leverage refinement types and polymorphism for synthesis, but it builds on a number of ideas from prior work as has been highlighted already throughout the paper. Specifically, our work combines ideas from two areas: synthesis of recursive functional programs and refinement type reconstruction.

Synthesis of recursive functional programs There have been a number of recent systems that target recursive functional programs and use type information in some form to restrict the search space. The most closely related to our work are MYTH [20], LEON [13] and SYNTREC [10], as well as Escher [1] and λ^2 [7].

MYTH pioneered the idea of leveraging bidirectional typechecking as a way to help the synthesizer prune the search space. However, MYTH does not support polymorphism or refinement types. Instead, the system relies on examples in order to specify the desired functionality. For certain functions, providing examples can be simpler than writing a refinement type, and whereas there are some functions for which we cannot write a refinement type in our

system, one can always provide more examples. That said, examples in general can never fully specify a program, so programming by example systems will always require a final step of manual checking to ensure that the generated solution is a correct one. Moreover, for some less intuitive problems, providing input output examples essentially requires that the programmer already know the algorithm and can step through it in her head—think red-black tree insertion, for example. Additionally, MYTH requires the set of examples provided to be *trace complete*, which means that for any example the user provides, there should also be examples corresponding to any recursive calls made on that input. EScher and λ^2 are also programming-by-example systems, so relative to our system, they also have the same advantages and disadvantages outlined above.

SYNTREC also represents a different set of tradeoffs compared to our system. For example, SYNTREC requires a template of an implementation, and its main focus is in making such templates reusable and easy to write. SYNTREC also relies on bounded checking, which allows it to tackle problems for which full verification would be extremely challenging, but it also means that it cannot provide strong correctness guarantees. Additionally, SYNTREC relies on being able to symbolically evaluate the program in its entirety, so it does not have the same modularity properties that refinement types afford. Like our system, SYNTREC also uses a combination of symbolic and explicit search, but with a much stronger bias towards symbolic search.

In LEON the search is guided by expressive specifications with recursive predicates, and verification is based on a semi-decision procedure [28] on top of SMT solvers. The general idea is similar to ours: first decompose the specification and then switch to guess-and-check mode. Like our system, it also does symbolic search in the guessing phase using CEGIS, as well as condition abduction. That said, decomposition and guess-and-check are not as integrated as they are in our work. In particular, the decomposition does not leverage type information, while the guessing phase uses types but only takes advantage of the specification at the top level. LEON also does not support polymorphism or high-order functions, so it also cannot take advantage of the strong restrictions imposed by polymorphic types. Overall, LEON is complementary to our system in the sense that they pick a different trade-off in terms of specification expressiveness vs. decidability, which makes our system less expressive but more predictable.

The use of type information has also proved extremely useful for code completion [9, 17, 21], although none of these systems rely on a type system as sophisticated as what is used in this paper, and they are designed for a very different set of tradeoffs compared to our system. For example, because the problem is highly under-constrained, these systems place significant emphasis on the ranking of solutions.

Another important body of work related to our approach is *hole driven development*, as embodied in systems like Agda [19], which also leverages a rich type system in order to aid development, but is meant to be used interactively rather than as a way to do complete synthesis. There have been similar efforts in Haskell, including the Djinn package which can generate Haskell expressions given a type [3]. However, Djinn is limited by the Haskell type system, which does not support refinement types.

Refinement type reconstruction Our refinement reconstruction is based on liquid types [12, 25, 29–31]: a type inference framework for general decidable refinement types. We integrate their ideas with bidirectional typechecking [23], which has been used before both for other flavors of refinement types [5, 6, 32] and for unrestricted dependent types [4], but not for general decidable refinement types. Another difference with liquid types is that we use greatest-fixed-point predicate abstraction procedure inspired by [27], and improved using an algorithm for efficient enumeration of all minimal unsatisfiable sets [16].
